Abstract
Sebaceous cell carcinoma is a rare cutaneous aggressive tumor arising from the sebaceous glands. Its almost exclusive site of occurrence is the eyelid but it has also been reported primarily in other sites, such as the parotid region. It is one of the most dangerous tumors, due to masquerading as inflammatory conditions, such as blepharoconjunctivitis, superior limbic keratoconjunctivitis or chalazion. It may also be misdiagnosed as other malignancies, while the incidence of metastasis is high-about 41%.

In our article we report a rare case of a recurrent sebaceous gland carcinoma of the eyelid with metastasis to the parotid gland and the regional lymph nodes.

In the review of the literature, diagnosis, treatment and the prognosis of this rare entity are described.

Introduction
Sebaceous cell carcinoma is a cutaneous aggressive tumor arising from the sebaceous glands. It is considered as the third most common eyelid malignancy after basal and squamous cell carcinomas. Its almost exclusive site of occurrence is the eyelid but it has also been reported primarily in other sites, such as the parotid region. Among western population it accounts for < 1-5.5%, while in Asians it can be observed at about 31-39% [1-7].

Sebaceous cells are predominantly present in meibomian glands of the tarsal plate, sebaceous glands of ocular adnexa (gland of Zeis), sebaceous glands embedded in caruncle, brow and associated hair follicles of lid skin. The most common site of occurrence is the upper eyelid.

It has been reported as the great masquerader, due to its resemblance to other benign or malignant lesions. In the differential diagnosis chalazion, blepharitis, conjunctivitis, basal cell carcinoma, squamous cell carcinoma, leukoplakia, ocular pemphigoid and carcinoma in-situ must be concerned [1,5,8-10].

We report a case of a parotid metastasis originating from a carcinoma of the upper eyelid, diagnosed as sebaceous cell carcinoma. Diagnosis and treatment of this entity are described.

Case Presentation
An 80-year-old Caucasian woman presented in our clinic with a firm, painless, slowly enlarging mass at her right parotid area with normal overlying skin. The patient had no regional palpable neck nodes. She also presented with a diffused eyelid, thickening in the upper right eyelid, painful in pulsation.

In her medical history she mentioned type I diabetes under medication. The patient had no history of tobacco or alcohol use. In her surgical history, she mentioned excision of a mass of the right lower eyelid four years ago, diagnosed as a squamous cell carcinoma of the skin of the eyelid, and which had been excised in whole, with histologically free margins of excision and depth invasion 4 mm. The patient had taken
that had been dissected, were positive for metastasis of the above carcinoma.

The patient underwent further radiotherapy and is under regular follow-up in the external unit of our clinic (Figure 4a, Figure 4b). There is no recurrence so far.

**Discussion**

Sebaceous carcinoma, sebaceous gland carcinoma (SGC), sebaceous cell carcinoma and meibomian gland carcinoma are all terms used in the literature to malignant neoplasm of
sebaceous origin. Sebaceous carcinoma is traditionally classified into two groups: Tumor arising from the ocular adnexa in the periocular area and those arising in the extraocular sites, which commonly involve the head and neck region, the parotid and submandibular glands, the external auditory canal, the trunk and laryngeal or pharyngeal cavities. It is considered to be the third most common eyelid malignancy — after basal cell and squamous cell carcinoma — representing 1-5.5% of all eyelid tumors. However, it is one of the most dangerous tumors, due to masquerading as inflammatory conditions, such as blepharoconjunctivitis, superior limbic keratoconjunctivitis or chalazion. It may also be misdiagnosed as other malignancies. The result is delayed diagnosis or wrong treatment [1,3,5,7-11].

In addition to its variable clinical appearance, a variable histologic appearance may also occur. As a result, delayed diagnosis or misdiagnosis following biopsy is not uncommon. Eyelid sebaceous gland carcinoma has a characteristic intraepithelial growth pattern, resulting from a pagetoid spread or a full-thickness replacement of the surface epithelium. The tumor may demonstrate well, moderately or poorly differentiated areas. The histologic examination may reveal a papillary or lobular growth pattern of neoplastic cells with evident sebaceous differentiation, or highly atypical neoplastic cells with prominent nuclear pleomorphism. Areas of necrosis and fibrosis are commonly found. The spread of the tumor in the form of infiltrating lobules, nests and cords is characteristic, perineural invasion is observed in about 20% of tumors, whereas vascular invasion is extremely infrequent [2,4,12-14].

The treatment of SGCs is adequate surgical excision with wide surgical margins and fresh frozen section controls. When the tumor diffuses the eyelid, orbital exenteration is required. Radical or selective neck dissection should be performed, to evaluate lymph node metastasis. Adjunctive radiotherapy or chemotherapy are necessary, depending on the stage of the tumor at the time of presentation, or when the surgical margins are diffused [1,3,6,8,9,11,13,15,16].

In our case, the patient presented with a parotid gland metastasis. Given her history of a surgical excision of a squamous cell carcinoma of the lower eyelid 4 years ago, the parotid gland tumor was thought to be a metastatic SCC. Unfortunately, we had no chance to histologically reexamine the

Figure 3: a) Conjunctival epithelium infiltrated by sebaceous gland carcinoma in situ. The neoplastic cells demonstrate sebaceous differentiation and a papillary growth pattern in this area. Uninvolved normal sebaceous glands are seen in the lower left corner. (x100); b) The carcinoma replaces the epithelium of the palpebral conjunctiva, exhibiting a papillary growth pattern (upper left corner), and extends to the conjunctival cul de sac and the bulbar conjunctiva (bottom) in a pagetoid fashion (arrows). (x100); c) In the well differentiated area (left) the neoplastic cells have vacuolated cytoplasm and form lobules, showing evident sebaceous differentiation (arrows), while the poorly differentiated area (right) consists of cells with variable size, more eosinophilic cytoplasm and prominent nuclear pleomorphism. A perineural invasion can be seen in the center (hooked arrow). (x100); d) Effacement of the architecture of the parotid gland due to metastasis of the carcinoma (upper right corner) (x100).
Well-differentiated tumors have a better prognostic outcome in comparison to the poorly differentiated. Confirmation of pagetoid spread is another bad prognostic factor. Other adverse prognostic features include the involvement of both upper and lower eyelid, tumor size more than 10 mm, orbital extension and infiltration of blood vessels and/or lymphatics [1,3,5-7,10].

Metastasis can occur by continuous growth, lymphatic spread or hematogenous spread. The most common sites of continuous growth is the orbit, the periauricular area and the parotid gland, as well as the regional lymph nodes of level I and II. More rare is distant metastasis to the lung, pleura, liver, brain, pericardium, lips, ethmoid sinus and skull. The overall mortality rate is 5 - 10%, while in cases of metastasis the rate may go up to 25% and up to 41% in cases where the duration of symptoms lasts more than six months [1,3,8,9,11-14].
