Abstract

The use of Solid Lipid Nanoparticles (SLN) has become a very popular approach in the development of innovative pharmaceutical drug delivery systems. The first step is the assessment of the lipids’ suitability. This paper is focused on the physicochemical characterization of lipids, namely cetyl alcohol and cetearyl alcohol, for the production of SLN. The bulk lipids were analyzed by Differential Scanning Calorimetry (DSC) and Wide Angle X-ray Diffraction (WAXD) without any treatment, after tempering the raw materials (bulk lipid) for 1 hour at 80 °C, and after their spray-drying process. Hydrophilic-Lipophilic Balance (HLB) values were determined using a combination of surfactants (polysorbate 20 and trioleate sorbitan) for the production of the hot o/w emulsion. Results of DSC and WAXD showed that after the thermal stress applied to the bulk lipids, both the melting point and the intensity of the refractogram peaks have decreased. Cetyl alcohol and cetearyl alcohol crystallized in more unstable polymorphic forms, which anticipate the suitability of these lipids for the production of SLN. The best HLB values obtained for the produced emulsions were 15.5, 16.0, and 16.7, combining accepted surfactants. The results showed that both cetearyl alcohol and cetyl alcohol are adequate lipids for the development of stable SLN.

Introduction

Solid Lipid Nanoparticles (SLN) are receiving great attention as pharmaceutical and cosmetic delivery systems. This fact is due to the production facilities and scale-up, regulatory acceptance of the raw materials [1-3], and marketing potential [4]. SLN may increase the bioavailability of drugs, reduce the risk of toxic effects, and promote sustained release [2,3,5].

The use of SLN as carriers for drugs for topical administration has been highlighted due to advantages over chemical degradation protection of the formulation of the active, hydration (occlusion of the stratum corneum) and enhanced penetration of drugs in the different layers, and promote the sustained release with
reduced systemic absorption and possess properties of photoprotection against UV light [6-10].

When applied onto the skin, SLN adhere to the skin’ surface, therefore are expected to prolong the contact time of the drug with the skin and enhance drug’s permeation [11]. SLN can be produced from lipids as triglycerides and their mixtures, fatty acids, and waxes [12-14].

Polymorphism is a phenomenon that can be demonstrated in lipids after the fusion process, recrystallization or in the production process [15]. It can lead to changes in pharmaceuticals compromising the drug stability, effectiveness and bioavailability [16]. The polymorphic changes can result in the impairment of the effect in vivo, defined as the presence of the same substance in different crystalline forms. Polymorphic characteristics influence the physicochemical properties. Under defined conditions of temperature and pressure, only one of the polymorphic is stable, other forms called metastable [17].

Polymorphism and crystallinity of the lipid raw-materials influence the drug’s encapsulation efficiency in SLN, as well as the drug retention in the lipid matrix during storage time [18]. Indeed, the drug may be expelled from the particle upon polymorphic transition from the form α (less stable) to the β form (more stable), an event that can easily take place during shelf-life of drug-loaded SLN [19]. When developing SLN, it is desirable to obtain particles with a less perfect matrix, to be able to load the drug molecules between lipid chains and imperfections of crystals [16,20]. However, the long-term stability of these less perfect matrices may be compromised if recrystallization occurs unpredictably. Depending on the type of lipids and production method, super-cooled melts, which are similar to o/w emulsions, may be obtained when the lipids remain in the liquid state dispersed in the aqueous phase, creating heterogeneous systems. These systems result from delayed recrystallization of the lipid [21].

The aim of this study was to evaluate the polymorphism and crystallinity of cetyl and cetearyl alcohol after melting the raw materials by tempering for 1 h at 80 °C, as well as their analysis after spray-drying process. The Hydrophilic-Lipophilic Balance (HLB) value for lipids was determined to reach the best combination of surfactants (tri oleate sorbitan and polysorbate 20) to obtain a stable emulsion during SLN production.

Material and Methods

Materials

Polysorbate 20 (Tween® 20) and ethanol were purchased from Synth (Diadema/SP, Brazil). Trioleate sorbitan (Span® 85), cetearyl alcohol (Crodacol® CS90) and cetyl alcohol (Crodacol® C90) were donated by Croda (Campinas/SP, Brazil). Double distilled water was used after filtration in a Millipore system (home supplied).

Methods

Thermal treatment of lipid materials: Lipids were subject to melting. The melting consisted of heating the sample up to 80 °C in a thermostatic water bath (Marconi, model MA 127/BD, Piracicaba/Brazil), following tempering by incubating the sample in the same bath for 1 h at 80 °C. Samples were then kept at room temperature until complete cooling and solidification, to check for the creation of polymorphic forms [18]. Then, the lipids were analyzed by Differential Scanning Calorimetry (DSC) and Wide Angle X-ray Diffraction (WAXD).

Spray-drying process: Lipids were solubilized in pure ethanol (1% m/v) at 30 °C under magnetic stirring (Tecnal-80 TE, Piracicaba/Brazil). A spray-dryer LM MSD 1.0 (Ribeirão Preto/Brazil) was used applying the following parameters: Feed rate of 14.1 mL/min, air flow 15 l/min, nozzle atomizer 1 mm air inlet temperature of 90 ± 5 °C; and temperature air outlet 50 ± 5 °C [22]. After the process, the samples were analyzed by DSC and WAXS.

Differential Scanning Calorimetry (DSC): Thermal behavior of lipid matrices was assessed by DSC (Shimadzu, DSC-60/60, Japan). A volume of sample containing approximately 5-10 mg of lipid mass was weighted in an aluminum pan and sealed hermetically, under inert atmosphere (N2), 45 ml/min. The analysis was performed at a heating and cooling rate of 5 K/min, using an empty pan as reference. The samples were heated from 10 °C up to 100 °C, following cooling down to 10 °C. Through the product software, the initial melting and crystallization temperatures (onset temperatures), the temperatures of endothermic and exothermic peaks, the final melting temperatures and crystallization temperatures (end set temperatures) and phase transition enthalpies (ΔH J.g-1) have been obtained [18].

Wide Angle X-ray diffraction (WAXD): To study the polymorphism and crystalline properties of the lipids, WAXD was carried out in a diffractometer X-ray (Philips, model X’pert, Pennsylvania, USA), using copper anode. WAXD measurements were taken from 5° to 40° in 0.015° steps (1 s per step). The interlayer spacing’s were calculated from the reflections using the Bragg’s equation:
to room temperature during 15 min under mechanical stirring (Tecnal TE 039/1, Piracicaba/Brazil). The emulsions were stored for 24 h at room temperature for further visual and optical microscopic analyses (Reichert-Jung, Series 150, Austria). The physical stability of the emulsions was evaluated by visual examination by phase separation or creaming.

Results

Cetyl and cetearyl alcohol were characterized before and after tempering and spray-drying treatment. Tempering was performed to mimic the production process carried out for SLN production using heat process [18]. Then, the spray dried was used to study the effect on their polymorphic and crystallization properties of lipid [24,25]. The characterization was done by DSC and WAXD [18,26-29]. DSC and WAXD were applied to the study of lipid matrices because of their complementarity data provision.

*Oil phase: Cetearyl alcohol or cetyl alcohol.

Figure 1 and Figure 2 show the thermograms of the melting (A) and crystallization (B) profiles recorded for cetyl alcohol of the samples submitted to tempering (a) and to spray-dry (b), in comparison to those without thermal treatment (c).

Assessment of Hydrophilic-Lipophilic Balance (HLB): For the assessment of the Hydrophilic-Lipophilic Balance (HLB), a series of 5 emulsions employing a combination of surfactant and co-surfactant with known HLB, to originate distinct HLB values [23] (Table 1). The aqueous phase consisted of water (95%, v/v) and surfactant (5% w/v). Trioleate sorbitan oleate (HLB = 1.8) and polysorbate 20 (HLB = 16.7) were used as surfactants. The oil phase consisted of cetearyl alcohol or cetyl alcohol (10% m/v). Then, the aqueous phase and oil phase were heated separately up to 80 °C using a thermostatic water bath (Marconi, model MA 127/BD, Piracicaba/Brazil). Aqueous phase was added to the oil phase under stirring (Ultra-Turrax® T25, USA), 10,000 rpm for 15 min. Then, the emulsions were cooled down to room temperature during 15 min under mechanical stirring (Tecnal TE 039/1, Piracicaba/Brazil). The emulsions were stored for 24 h at room temperature for further visual and optical microscopic analyses (Reichert-Jung, Series 150, Austria). The physical stability of the emulsions was evaluated by visual examination by phase separation or creaming.
The WAXD features the crystal structure and/or polymorphic materials, identifying the interactions between the incident x-ray beam and the electrons of the component atoms in the sample to be analyzed by detecting the diffracted photons. Cetyl alcohol and cetearyl alcohol were performed by WAXD analysis (Figure 3).

Cety alcohol treatment showed 2 melting peaks, the first started at 34.54 °C and finished at 48.58 °C, the melting point was 43.76 °C, and the heat capacity was -54.84 J·g⁻¹. The second peak started at 49.72 °C and finished at 58.24 °C, the melting point was 53.89 °C and the heat capacity was -115.83 J·g⁻¹. The cooling peak occurred in the crystallization temperature 47.95 °C and 26.96 °C. After the tempering, cetyl alcohol showed a melting point at 49.49 °C, with the onset at 41.42 °C and the endset at 49.49 °C. The heat flow was -204.42 J·g⁻¹. In the cooling curve two peaks were recorded at 44.45 °C and 38.34 °C, respectively. The first peak started at 29.99 °C and finished at 42.71 °C with melting point in 37.71 °C and heat flow in -56.25 J·g⁻¹. The second peak started at 45.40 °C and finished at 56.74 °C. The melting point was 52.98 °C and the flow rate was -118.04 J·g⁻¹. The 2 cooling peaks occurred at the crystallization temperatures of 48.08 °C and 26.16 °C, respectively.

Figure 2: DSC thermograms of melting (A) and crystallization (B) profiles recorded for cetearyl alcohol of the samples submitted to tempering (a) and to spray-dry (b), in comparison to those without thermal treatment (c).

Figure 3: WAXD analysis of untreated cetyl alcohol (A), untreated cetearyl alcohol (B), cetyl alcohol after tempering for 1 hour at 80 °C (C), cetearyl alcohol after tempering for 1 hour at 80 °C (D), cetyl alcohol after spray-drying (E), and of cetearyl alcohol after spray-drying (F).
The WAXD patterns show that after tempering cetyl alcohol and cetearyl alcohol, the intensity of the peaks was reduced. No defined width was observed after treatment. From the WAXD analysis, cetyl alcohol depicted two distinct polymorphic forms, whereas only one form was observed by DSC analysis, giving the similar melting points of both polymorphs.

The small difference of diffractograms is observed in interlayer spacings. Cetyl alcohol showed 21.75 (2θ) i.e. d = 0.223 nm, and 24.68 (2θ) i.e. d = 1.31 nm without process; 21.36 (2θ) i.e. d = 0.227 nm and 24.17 (2θ) i.e. d = 0.2062 nm before tempering. Cetearyl alcohol showed 21.33 (2θ) i.e. d = 0.227 nm, and 24.12 (2θ) i.e. d = 0.206 nm untreated; 21.41 (2θ) i.e. d = 0.226 nm and 24.17 (2θ) i.e. d = 0.2062 nm before tempering. In WAXD analysis, the peak was kept but with decreased intensity, results that are in agreement with those obtained for DSC. The stable form β decreased after spray drying treatment.

Figure 4 shows the HLB values obtained for stable emulsions produced from cetyl alcohol and cetearyl alcohol.

Figure 5 shows the results of the optical microscopic analyses (100-fold increase) from cetyl alcohol and...
cetearyl alcohol emulsions with HLB 15.5. A smooth and homogeneous structure was observed.

**Discussion**

A variety of production methods are used to develop SLN. The main method is the High-Pressure Homogenization because it is easy to scale up and it has been used for a long time to produce emulsions for parenteral nutrition [32]. With this methodology, it is possible to control the mean diameter and the polydispersity index of SLN, avoiding the use of organic solvents [33]. The employment of high temperatures in this method can modify the crystal structures of lipids, causing differences in formulation after solidification compared to the material previously studied [34].

The International Conference on Harmonization (ICH) of Technical Requirements for Registration of Pharmaceuticals for Human Use, composed of representatives of the European Union, Japan, the United States and representatives of the pharmaceutical industry, establishes the protocols for quality control of pharmaceutical ingredients, published as guides or laws in several countries. The guide published by the American agency Food and Drug Administration (FDA), establishes the criteria for the characterization of the polymorphic form and level of criticality on the final product. The techniques listed this characterization are WAXD, DSC, microscopy and spectroscopy [35].

Lipids suffer polymorphism, thereby it has ability to solidify in different crystalline forms, with significant physical and chemical changes in form, solubility, melting point and crystallization. Amorphous matrix showed disordered arrangements of molecules, favoring the high loading of the drug. In the crystalline matrix, the crystals form organized arrangements of molecules with fixed repeating unit of unit cells [34]. Standard WAXD may identify polymorphs. Long spaces provide information about the distance between the crystal planes (chain length), while the short spacing’s provide information about the structure of the sub-cell (distance between chains). Lipids widely used in the production of SLN and NLC are typical examples of molecules that commonly present three distinct and important polymorphic forms, α and β´ or α, β´ and β respectively, according to the structure of the subcell. The α form (hexagonal) is the least stable, with lower melting point and latent heat. The form β (tricyclic) is more stable with higher melting point and higher latent heat. The transformation of α to β´ (orthorhombic) and β this to occur in this order and are irreversible [36]. It is fundamental to know the physical form of the crystal habit of lipids to produce stable SLN.

Cetyl alcohol and cetearyl alcohol are biocompatible lipids and of Generally Regarded as Safe (GRAS) status. They have been used as raw materials for the production of SLN [31,37], o/w emulsions [38] and microparticles [39]. Cetyl alcohol is produced from vegetable oils coconut or palm kernel. It is characterized as an alcohol with functional group OH (hydrophilic) and long chain with 16 carbons (lipophilic). Cetearyl alcohol consisting predominantly of cetyl and stearyl alcohols mixture, and it is classified as a fatty alcohol composed CH₃(CH₂)ₙOH; n = variable, typically 15-17.

The differences between the melting and the onset temperatures of cetyl alcohol before (10.65 °C) and after tempering (8.07 °C) are slower after the tempering process. These values suggesting changes from a more unstable polymorphic form. According to the chemical nature of the lipid, there may be modifications in the fractions of the polymorphs present in the composition of the nanoparticles, which leads to the reduction, displacement or change in the melting temperature of the system.

For cetearyl alcohol, the first peak was recorded at 14.04 °C and 8.52 °C before and after tempering, respectively, while the second peak was obtained at 8.52 °C and 11.34 °C before and after tempering, respectively. It is known that the melting peak of the lipid occurs between the onset and endset temperatures, and the greater the difference between onset and endset temperatures, the greater the disorder of the crystals. Cetyl alcohol depicted a short difference between onset and endset temperatures, therefore suggesting a decrease of the crystalline arrangements. Cetearyl alcohol showed the presence of two peaks, where the decrease of the first peak and increase of the second peak was attributed to the mixture of cetyl and stearyl alcohols existing in this lipid arranged in different form [40].

After tempering, the onset temperature decreased for both lipids. These informations suggest the presence of β/βi caused by the thermal stress in the lipid [16].

The tempering process of cetyl alcohol decreased the melting enthalpy in 20% (255.41 to 204.42 J.g⁻¹), indicating significant disruptions in the microstructure. After tempering, the energy was lower, and the lipid changed from a more stable to a more unstable polymorphic form. Cetaryl alcohol did not show a significant difference on the enthalpy. However, in both lipids, the peaks were maintained after tempering, but the intensity of peaks was lower after tempering. This fact suggests lower crystallization when compared without treatment. Tempering affected the recrystallization of lipids. However, these results are agreement with polymorphism existing in the lipids [41].

Crystallinity is a property of lipids, and this has been
studied before and after tempering the bulk materials for 1 h at 80 °C. The peaks observed in lipids are in β’ form, identified by the spacings between 0.42-0.43 nm and 0.37-0.40 nm. Comparing the results obtained by DSC and WAXD it is possible to see that after tempering, the decrease of the melting point and intensity of WAXD peaks demonstrated the presence of a less stable crystalline lipid. These demonstrates agreement between the DSC and WAXD results, confirming that after tempering the peak of β’/β increases.

It is important to realize that the three-dimensional organization that acquires lipid matrix during solidification depends on the cooling rate of lipids and their composition. It is a very important factor for the loading of the drug molecules in SLN. When the cooling rate is slow, the hydrocarbon chains of lipids can be rearranged in a more ordered and stable form. This study was carried out at temperature. On the contrary, when the cooling rate is high, the solidification of the matrix also occurs rapidly, rearranging into a more unstable polymorph type. Thus, the preparation of SLN by hot High-pressure homogenization follow high stability polymorphs. These demonstrates agreement between the DSC and WAXD results, confirming that after tempering the peak of β’/β increases. 

In the crystalline matrix, the crystals form organized arrangements of molecules with fixed repeating array built of unit cells [41]. Standard WAXD may identify these polymorphs. The WAXS profile for cetyl alcohol are shown in Figure 3A, Figure 3C and Figure 3E and correspond to untreated lipid, after tempering, and after spray-drying, respectively.

The diffraction patterns of sample (A) display non-equidistant reflections (peaks X and Y) in comparison to sample (A) and (E). The scattering angle ranging between 5.0° and 18° (2θ) and these peaks are indicative of a non-periodic lamellar arrangement within the lipid structure suggesting tempering process influence polymorphism of lipid. Therefore, in all samples of cetyl alcohol a difference in width and intensity of peaks was observed. Sample (A) shows one reflection at Bragg spacing values of 0.585 nm, 21.72 (2θ). After tempering (C) and spray-drying (E) Bragg’s spacing values of 0.280 nm and 0.424 nm were observed, which is indicative of the presence of β’ polymorphic modification with the characteristic spacings between 0.42-0.43 nm and 0.37-0.40 nm.

Results also showed that samples B, D and F, prepared with Cetearyl alcohol without tempering, after tempering, and after dried sprried process, respectively, different width of the peaks and the intensity. It is observed that presence of characteristic peaks for all, however there is a significant increase of intensity when compared with the untreated sample.

The WAXS profile for cetearyl alcohol are shown in Figure 3B, Figure 3D and Figure 3F and correspond to untreated lipid, after tempering, and after spray-drying, respectively. Differences in the peaks width and intensity have been observed between the samples. Characteristic peaks occurring in the same temperature have been recorded but with a significant increase of the intensity when compared to the sample without treatment.

In all samples without treatment, a minor intensity peak was recorded, which suggests the formation of more crystallinity polymorphs. This condition translates a higher thermodynamic stability of the system.

Long-term stability of emulsions, surfactants are adsorbed at the interface o/w to form a film, which
decreases the surface tension [46]. The stability of the pre-emulsions after 24 hours were obtained with HLB of 15.5; 16.0 e 16.7 assessed for the two lipids. These values were consistent with the data obtained by manufacturers. The formulations with HLB de 14.1 and 15.0 showed separated phase. It is therefore desirable to operate with a surfactant composition of polysorbate 20 and trioleate sorbitan of HLB around 15.5 for the production of stable and homogeneous SLN.

The numbers corresponding to the HLB of some products are obtained from the literature. Lipids shows HLB between 6 and 17. The development of stable emulsion systems significantly because it is important and a useful, easy and practical methodology to forecast a stable SLN production.

Conclusions

DSC and WAXD are valuable tools to assess the presence of polymorphs in fatty alcohol crystals. Cetyl and cetearyl alcohol suffer polymorphic modification with tempering and spray dried process. Polymorphic structure of lipid suggesting a more unstable form being good options for loading drugs in SLN. Indeed, the high amount of β and β' decreased after tempering and spray drying process, changing the thermodynamic stability and favoring the loading of drugs in SLN. Also, the HLB allowed the selection of the best combination of surfactants, for the development of homogeneous and stable emulsions. The stable emulsion was obtained with a suitable mixture of polysorbato 20 and trioleate sorbitan with the best HLB values were 15.5, 16.0, and 16.7. The results showed that both cetearyl alcohol and cetyl alcohol promising to development SLN stable for drug delivery because produced a disorganized matrix able to be loading high amount of drug.
